A Space Consumption Analysis By Abstract Interpretation *

Manuel Montenegro, Ricardo Peña and Clara Segura montenegro@fdi.ucm.es {ricardo,csegura}@sip.ucm.es

Universidad Complutense de Madrid, Spain

Abstract. Safe is a first-order functional language with an implicit region-based memory system and explicit destruction of heap cells. Its static analysis for inferring regions, and a type system guaranteeing the absence of dangling pointers have been presented elsewhere.

In this paper we present a new analysis aimed at inferring upper bounds for heap and stack consumption. It is based on abstract interpretation, being the abstract domain the set of all *n*-ary monotonic functions from real non-negative numbers to a real non-negative result. This domain turns out to be a complete lattice under the usual \sqsubseteq relation on functions. Our interpretation is monotonic in this domain and the solution we seek is the least fixpoint of the interpretation.

We first explain the abstract domain and some correctness properties of the interpretation rules with respect to the language semantics, then present the inference algorithms for recursive functions, and finally illustrate the approach with the upper bounds obtained by our implementation for some case studies.

1 Introduction

The first-order functional language Safe has been developed in the last few years as a research platform for analysing and formally certifying two properties of programs related to memory management: absence of dangling pointers and having an upper bound to memory consumption. Two features make Safe different from conventional functional languages: (a) a region based memory management system which does not need a garbage collector; and (b) a programmer may ask for explicit destruction of memory cells, so that they could be reused by the program. These characteristics, together with the above certified properties, make Safe useful for programming small devices where memory requirements are rather strict and where garbage collectors are a burden in service availability.

The Safe compiler is equipped with a battery of static analyses which infer such properties [12, 13, 10]. These analyses are carried out on an intermediate language called *Core-Safe* explained below. We have developed a resource-aware operational semantics of *Core-Safe* [11] producing not only values but also exact figures on the heap and stack consumption of a particular running. The code generation phases have been certified in a proof assistant [5, 4], so that there is

^{*} Work partially funded by the projects TIN2008-06622-C03-01/TIN (STAMP), S-0505/ TIC/ 0407 (PROMESAS) and the MEC FPU grant AP2006-02154.

a formal guarantee that the object code actually executed in the target machine (the JVM [9]) will exactly consume the figures predicted by the semantics.

Regions are dynamically allocated and deallocated. The compiler 'knows' which data lives in each region. Thanks to that, it can compute an upper bound to the space consumption of every region and so and upper bound to the total heap consumption. Adding to this a stack consumption analysis would result in having an upper bound to the total memory needs of a program.

In this work we present a static analysis aimed at inferring upper bounds for individual Safe functions, for expressions, and for the whole program. These have the form of *n*-ary mathematical functions relating the input argument sizes to the heap and stack consumption made by a Safe function, and include as particular cases multivariate polynomials of any degree. Given the complexity of the inference problem, even for a first-order language like Safe, we have identified three separate aspects which can be independently studied and solved: (1) Having an upper bound on the size of the call-tree deployed at runtime by each recursive Safe function; (2) Having upper bounds on the sizes of all the expressions of a recursive Safe function. These are defined as the number of cells needed by the normal form of the expression; and (3) Given the above, having an inference algorithm to get upper bounds for the stack and heap consumption of a recursive Safe function.

Several approaches to solve (1) and (2) have been proposed in the literature (see the Related Work section). We have obtained promising results for them by using rewriting systems termination proofs [10]. In case of success, these tools return multivariate polynomials of any degree as solutions. This work presents a possible solution to (3) by using abstract interpretation. It should be considered as a *proof-of-concept* paper: we investigate how good the upper bounds obtained by the approach are, provided we have the best possible solutions for problems (1) and (2). In the case studies presented below, we have introduced by hand the bounds to the call-tree and to the expression sizes.

The abstract domain is the set of all monotonic, non-negative, *n*-ary functions having real number arguments and real number result. This infinite domain is a complete lattice, and the interpretation is monotonic in the domain. So, fixpoints are the solutions we seek for the memory needs of a recursive *Safe* function. An interesting feature of our interpretation is that we usually start with an over-approximation of the fixpoint, but we can obtain tighter and tighter safe upper bounds just by iterating the interpretation any desired number of times.

The plan of the paper is as follows: Section 2 gives a brief description of our language; Section 3 introduces the abstract domain; Sections 4 and 5 give the abstract interpretation rules and some proof sketches about their correctness, while Section 6 is devoted to our inference algorithms for recursive functions; in Section 7 we apply them to some case studies, and finally in Section 8 we give some account on related and future work.

2 Safe in a Nutshell

Safe is polymorphic and has a syntax similar to that of (first-order) Haskell. In *Full-Safe* in which programs are written, regions are implicit. These are inferred

when *Full-Safe* is desugared into *Core-Safe* [13]. The allocation and deallocation of regions is bound to function calls: a *working region* called *self* is allocated when entering the call and deallocated when exiting it. So, at any execution point only a small number of regions, kept in an invocation stack, are alive. The data structures built at *self* will die at function termination, as the following treesort algorithm shows:

```
treesort xs = inorder (mkTree xs)
```

First, the original list xs is used to build a search tree by applying function mkTree (not shown). The tree is traversed in inorder to produce the sorted list. The tree is not part of the result of the function, so it will be built in the working region and will die when the treesort function returns. The *Core-Safe* version of treesort showing the inferred type and regions is the following:

Variable r of type rho2 is an additional argument in which treesort receives the region where the output list should be built. This is passed to the inorder function. However self is passed to mkTree to instruct it that the intermediate tree should be built in treesort's *self* region.

Data structures can also be destroyed by using a destructive pattern matching, denoted by !, or by a **case!** expression, which deallocates the cell corresponding to the outermost constructor. Using recursion, the recursive portions of the whole data structure may be deallocated. As an example, we show a *Full-Safe* insertion function in an ordered list, which reuses the argument list's spine:

Expression ys! means that the substructure pointed to by ys in the heap is reused. The following is the (abbreviated) Core-Safe typed version:

This function will run in constant heap space since, at each call, a cell is destroyed while a new one is allocated at region \mathbf{r} by the (:) constructor. Only when the new element finds its place a new cell is allocated in the heap.

In Fig. 1 we show two Core-Safe big-step semantic rules in which a resource vector is obtained as a side effect of evaluating an expression. A judgement has the form $E \vdash h, k, td, e \Downarrow h', k, v, (\delta, m, s)$ meaning that expression e is evaluated in an environment E using the td topmost positions in the stack, and in a heap

$E \vdash h, k, 0, e_1 \Downarrow h', k, v_1, (\delta_1, m_1, s_1) E \uplus [x_1 \mapsto v_1] \vdash h', k, td + 1, e_2 \Downarrow h'', k, v, (\delta_2, m_2, s_2) $	of 1
$\overline{E \vdash h, k, td, \mathbf{let} \ x_1 = e_1 \ \mathbf{in} \ e_2 \Downarrow h'', k, v, (\delta_1 + \delta_2, \max\{m_1, \delta_1 + m_2\}, \max\{2 + s_1, 1 + s_2\})} \overset{[L]}{=}$	$Let_1]$
$E \ x = p C = C_r E \uplus [\overline{x_{r_i} \mapsto v_i}^{n_r}] \vdash h, k, td + n_r, e_r \Downarrow h', k, v, (\delta, m, s)$	— [Case!]
$\overline{E \vdash h \uplus [p \mapsto (j, C \ \overline{v_i}^n)]}, k, td, \textbf{case!} \ x \ \textbf{of} \ \overline{C_i \ \overline{x_{ij}}^{n_i} \rightarrow e_i}^n \Downarrow h', k, v, (\delta + [j \mapsto -1], \max\{0, m-1\}, s + i) \parallel b' \mid b'$	$\overline{n_r}$ [Case.]

Fig. 1. Two rules of the resource-aware operational semantics of Safe

(h,k) with 0..k active regions. As a result, a heap (h',k) and a value v are obtained, and a resource vector (δ, m, s) is consumed. A heap h is a mapping between pointers and constructor cells $(j, C \ \overline{v_i}^n)$, where j is the cell region. The first component of the resource vector is a partial function $\delta : \mathbb{N} \to \mathbb{Z}$ giving for each active region i the signed difference between the cells in the final and initial heaps. A positive difference means that new cells have been created in this region. A negative one, means that some cells have been destroyed. By $dom(\delta)$ we denote the subset of \mathbb{N} in which δ is defined. By $|\delta|$ we mean the sum $\sum_{n \in dom(\delta)} \delta(n)$ giving the total balance of cells. The remaining components m and s respectively give the *minimum* number of fresh cells in the heap and of words in the stack needed to successfully evaluate e. When e is the main expression, these figures give us the total memory needs of a particular run of the *Safe* program. For a full description of the semantics and the abstract machine see [11].

3 Function Signatures

A Core-Safe function is defined as a n + m argument expression:

$$f :: t_1 \to \dots t_n \to \rho_1 \to \dots \rho_m \to t$$
$$f x_1 \cdots x_n @ r_1 \cdots r_m = e_f$$

A function may charge space costs to heap regions and to the stack. In general, these costs depend on the *sizes* of the function arguments, where the size of a term of an algebraic type is the number of cells of its recursive spine, the size of a natural number is its value, and the size of a boolean value is zero. For example,

copy xs @ r = case xs of [] -> [] @ r y:ys -> let zs = copy ys @ r in let rs = (x:zs) @ r in rs

charges as many cells to region r as the length of its input list.

As a consequence, all the space costs and needs of f can be expressed as nary functions $\eta : (\mathbb{R}^+ \cup \{+\infty\})^n \to \mathbb{R} \cup \{+\infty, -\infty\}$. Infinite costs will be used to represent that we are not able to infer a bound (either because it does not exist or because the analysis is not capable). Costs can be negative if the function destroys more cells than it builds. Currently we are restricting ourselves to functions where for each destructed cell at least a new cell is built in the same region. This covers many interesting functions where the aim of cell destruction is space reuse instead of pure destruction, e.g. function **insertD** shown in the previous section. This restriction means that the domain of the space cost functions is the following:

$$\mathbb{F} = \{\eta : (\mathbb{R}^+ \cup \{+\infty\})^n \to \mathbb{R}^+ \cup \{+\infty\} \mid \eta \text{ is monotonic} \}$$

The domain $(\mathbb{F}, \sqsubseteq, \bot, \top, \sqcup, \sqcap)$ is a complete lattice, where \sqsubseteq is the usual order between functions, and the rest of components are standard. Notice that it is closed by the operations $\{+, \sqcup, *\}$. By abuse of notation we abbreviate $\lambda \overline{x_i}^n . c$ by just c, where $c \in \mathbb{R}^+$.

Function f above may charge space costs to a maximum of n+m+1 regions: It may destroy cells in the regions where $x_1
dots x_n$ live; it may create/destroy cells in any output region $r_1
dots r_m$, and additionally in its *self* region. Each region r has a region type ρ . We denote by R_{in}^f the set of input region types, and by R_{out}^f the set of output region types. For example, $R_{in}^{treesort} = \{\rho_1\}$ and $R_{out}^{treesort} = \{\rho_2\}$. Looked from outside, the charges to the *self* region are not visible, as this region disappears when the function returns.

Summarising, let $R_f = R_{in}^f \cup R_{out}^f$. Then $\mathbb{D} = \{\Delta : R_f \to \mathbb{F}\}$ is the complete lattice of functions that describe the space costs charged by f to every visible region. In the following we will call abstract heaps to the functions $\Delta \in \mathbb{D}$.

Definition 1. A function signature for f is a triple $(\Delta_f, \mu_f, \sigma_f)$, where Δ_f belongs to \mathbb{D} , and μ_f, σ_f belong to \mathbb{F} .

The aim is that Δ_f describes (an upper bound to) the space costs charged by f to every visible region, and μ_f, σ_f respectively describe (an upper bound to) the heap and stack *needs* of f in order to execute it without running out of space. By $[]_f$ we denote the empty function $\lambda \rho . \lambda \overline{x_i}^n . 0$, where we assume $\rho \in R_f$. By $|\Delta|$ we mean $\sum_{\rho \in dom(\Delta)} \Delta \rho$.

4 Abstract Interpretation

In Figure 2 we show the abstract interpretation rules for the most relevant Core-Safe expressions. There, an atom a represents either a variable x or a constant c, and |e| denotes the function obtained by the size analysis for expression e. We can assume that the abstract syntax tree is decorated with such information.

When inferring an expression e, we assume it belongs to the body of a function definition $f \ \overline{x_i}^n \ @ \ \overline{r_j}^m = e_f$, that we will call the *context* function, and that only already inferred functions $g \ \overline{y_i}^l \ @ \ \overline{r_j}^q = e_g$ are called. Let Σ be a global environment giving, for each Safe function g in scope, its signature $(\Delta_g, \mu_g, \sigma_g)$, let Γ be a typing environment containing the types of all the variables appearing in e_f , and let td be a natural number. The abstract interpretation $[\![e]\!] \Sigma \Gamma td$ gives a triple (Δ, μ, σ) representing the space costs and needs of expression e. The statically determined value td occurring as an argument of the interpretation and used in rule App is the size of the top part of the environment used when compiling the expression $g \ \overline{a_i}^l \ @ \ \overline{r_j}^q$. This size is also an argument of the operational semantics. See [11] for more details.

Rules [Atom] and [Primop] exactly reflect the corresponding resource-aware semantic rules [11]. When a function application $g \overline{a_i}^l @ \overline{r_j}^q$ is found, its signature Σg is applied to the sizes of the actual arguments, $\overline{|a_i| \overline{x_j}^n}^l$ which have the

$\llbracket a \rrbracket \varSigma \Gamma \ td = (\llbracket]_f, 0, 1) [Atom]$
$\llbracket a_1 \oplus a_2 \rrbracket \varSigma \varGamma td = (\llbracket]_f, 0, 2) [Primop]$
$\begin{split} \Sigma \ g &= (\Delta_g, \mu_g, \sigma_g) \qquad \theta = unify \ \Gamma \ g \ \overline{a_i}^l \ \overline{r_j}^q \\ \mu &= \lambda \overline{x}^n.\mu_g \ (\overline{ a_i \ \overline{x}^n}^l) \qquad \sigma = \lambda \overline{x}^n.\sigma_g \ (\overline{ a_i \ \overline{x}^n}^l) \qquad \Delta = \theta \downarrow_{\overline{ a_i \ \overline{x}^n}^l} \ \Delta_g \end{split}$
$\frac{\mu = \lambda \overline{x}^n \cdot \mu_g \left(a_i \ \overline{x}^n \right)}{\left[\sigma = \lambda \overline{x}^n \cdot \sigma_g \left(a_i \ \overline{x}^n \right) - \Delta = \theta \right]_{\overline{ a_i \ \overline{x}^n }} \Delta_g}{\left[App \right]}$
$\ g \ \overline{a_i}^{\iota} \ @ \ \overline{r_j}^{q}\ \ \Sigma \ \Gamma \ td = (\Delta, \mu, \sqcup \{l+q, \sigma - \ td + l+q\})$
$ \begin{array}{ccc} \llbracket e_1 \rrbracket \varSigma \ \varGamma \ 0 = (\varDelta_1, \mu_1, \sigma_1) & \llbracket e_2 \rrbracket \varSigma \ \varGamma \ (td+1) = (\varDelta_2, \mu_2, \sigma_2) \\ \hline \llbracket \operatorname{let} x_1 = e_1 \ \operatorname{in} \ e_2 \rrbracket \varSigma \ \varGamma \ td = (\varDelta_1 + \varDelta_2, \sqcup \{\mu_1, \varDelta_1 + \mu_2\}, \sqcup \{2 + \sigma_1, 1 + \sigma_2\}) \end{array} \begin{bmatrix} Let_I \rrbracket \end{array} $
$\Gamma r = \rho \llbracket e_2 \rrbracket \Sigma \Gamma (td+1) = (\Delta, \mu, \sigma) $ $\llbracket Let_2 \rrbracket$
$\boxed{\left[\text{let } x_1 = C \ \overline{a_i}^n \ @ r \ \text{in } e_2 \right] \ \varSigma \ f \ td} = \left(\Delta + [\rho \mapsto 1], \mu + 1, \sigma + 1 \right) \ \left[Let_2 \right]$
$(\forall i) \ \llbracket e_i \rrbracket \varSigma \Gamma \ (td + n_i) = (\varDelta_i, \mu_i, \sigma_i) $ $[Case]$
$\boxed{\left[\text{case } x \text{ of } \overline{C_i \ \overline{x_{ij}}^{n_i} \to e_i}^n \right] \Sigma \ \Gamma \ td = \left(\bigsqcup_{i=1}^n \Delta_i, \bigsqcup_{i=1}^n \mu_i, \bigsqcup_{i=1}^n (\sigma_i + n_i) \right)} $
$\Gamma x = T\overline{t_k}^{l} @\rho (\forall i) \ \llbracket e_i \rrbracket \varSigma \Gamma \ (td + n_i) = (\Delta_i, \mu_i, \sigma_i) $ [Case!]
$\begin{bmatrix} \text{case! } x \text{ of } \overline{C_i \ \overline{x_{ij}}^{n_i} \to e_i}^n \end{bmatrix} \varSigma \ \Gamma \ td = \left([\rho \mapsto -1] + \bigsqcup_{i=1}^n \Delta_i, \sqcup (0, \bigsqcup_{i=1}^n \mu_i - 1), \bigsqcup_{i=1}^n (\sigma_i + n_i) \right) $

Fig. 2. Space inference rules for expressions with non-recursive applications

 \overline{x}^n as free variables. Due to the application, some different region types of g may instantiate to the same actual region type of f. That means that we must accumulate the memory consumed in some formal regions of g in order to get the charge to an actual region of f. In Figure 2, $unify \ \Gamma \ g \ \overline{a_i}^l \ \overline{r_j}^q$ computes a substitution θ from g's region types to f's region types. If $\theta \ \rho_g = \rho_f$, this means that the generic g's region type ρ_g is instantiated to the f's actual region type ρ_f . Formally, if $R_g = R_{in}^g \cup R_{out}^g$ then $\theta :: R_g \to R_f \cup \{\rho_{self}\}$ is total. The extension of region substitutions to types is straightforward.

Definition 2. Given a type environment Γ , a function g and the sequences $\overline{a_i}^l$ and $\overline{r_j}^q$, we say that $\theta = unify \ \Gamma \ g \ \overline{a_i}^l \ \overline{r_j}^q$ iff

$$\Gamma g = \forall \overline{\alpha}.\overline{t_i}^l \to \overline{\rho_j}^q \to t \text{ and } \forall i \in \{1...l\}. \theta \ t_i = \Gamma \ a_i \text{ and } \forall j \in \{1...q\}. \theta \ \rho_j = \Gamma \ r_j$$

As an example, let us assume $g :: ([a]@\rho_1^g, [[b]@\rho_2^g]@\rho_1^g)@\rho_3^g \to \rho_2^g \to \rho_4^g \to \rho_5^g \to t$ and consider the application $g p @ r_2 r_1 r_1$ where $p :: ([a]@\rho_1^f, [[b]@\rho_2^f]@\rho_1^f)@\rho_1^f, r_1 :: \rho_1^f$ and $r_2 :: \rho_2^f$. The resulting substitution would be:

$$\boldsymbol{\theta} = [\rho_1^g \mapsto \rho_1^f, \rho_2^g \mapsto \rho_2^f, \rho_3^g \mapsto \rho_1^f, \rho_4^g \mapsto \rho_1^f, \rho_5^g \mapsto \rho_1^f]$$

The function $\theta \downarrow_{\overline{\eta_i \ x^{n^l}}} \Delta_g$ converts an abstract heap for g into an abstract heap for f. It is defined as follows:

$$\theta \downarrow_{\overline{\eta_i \ \overline{x_j}}^n} \Delta_g = \lambda \rho \ . \ \lambda \overline{x_j}^n . \sum_{\substack{\rho' \in R_g \\ \theta \ \rho' = \rho}} \Delta_g \ \rho' \ \overline{\eta_i \ \overline{x_j}^n}^l \qquad (\rho \in R_f \cup \{\rho_{self}\}, \eta_i \in \mathbb{F})$$

In the example, we have:

$$\Delta \rho_{1}^{f} = \lambda \overline{x}^{n} \cdot \Delta_{g} \rho_{2}^{g} \frac{\overline{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}}}{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}} \\ \Delta \rho_{1}^{f} = \lambda \overline{x}^{n} \cdot \Delta_{g} \rho_{1}^{g} \frac{\overline{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}}}{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}} + \Delta_{g} \rho_{3}^{g} \frac{\overline{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}}}{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}} + \Delta_{g} \rho_{5}^{g} \frac{\overline{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}}}{\left(\left|a_{i}\right| \overline{x}^{n}\right)^{l}}$$

Rules $[Let_1]$ and $[Let_2]$ reflect the corresponding resource-aware semantic rules in [11]. Rules [Case] and [Case!] use the least upper bound operators | | in order to obtain an upper bound to the charge costs and needs of the alternatives.

$\mathbf{5}$ **Correctness of the Abstract Interpretation**

Let $f \ \overline{x_i}^n \ @ \ \overline{r_j}^m = e_f$, be the *context* function, which we assume well-typed according to the type system in [12]. Let us assume an execution of e_f under some E_0, h_0, k_0 and td_0 :

$$E_0 \vdash h_0, k_0, td_0, e_f \Downarrow h_f, k_0, v_f, (\delta_0, m_0, s_0)$$
(1)

In the following, all \Downarrow -judgements corresponding to a given sub-expression of e_f will be assumed to belong to the derivation of (1).

The correctness argument is split into three parts. First, we shall define a notion of *correct signature* which formalises the intuition of the inferred (Δ, μ, σ) being an upper bound of the actual (δ, m, s) . Then we prove that the inference rules of Figure 2 are correct, assuming that all function applications are done to previously inferred functions, that the signatures given by Σ for these functions are correct, and that the size analysis is correct. Finally, the correctness of the signature inference algorithm is proved, in particular when the function being inferred is recursive.

In order to define the notion of correct signature we have to give some previous definitions. We consider region instantiations, denoted by Reg, Reg',..., which are partial mappings from region types ρ to natural numbers *i*. Region instantiations are needed to specify the actual region i to which every ρ is instantiated at a given execution point. A instantiation Req is consistent with a heap h, an environment E and a type environment Γ if Req does not contradict the region instantiation obtained at runtime from h, E and Γ , i.e. common type region variables are bound to the same actual region. Formal definition of consistency can be found in [12], where we also proved that if a function is well-typed, consistency of region instantiations is preserved along its execution.

Definition 3. Given a pointer p belonging to a heap h, the function size returns the number of cells in h of the data structure starting at p:

$$size(h[p \mapsto (j, C \ \overline{v_i}^n)], p) = 1 + \sum_{i \in RecPos(C)} size(h, v_i)$$

where RecPos(C) denotes the recursive positions of constructor C.

We assume that size(h, c) = 0 for every heap h and constant c.

Definition 4. Given a sequence of sizes $\overline{s_i}^n$ for the input parameters, a number k of regions and a region instantiation Req, we say that

- Δ is an upper bound for δ in the context of $\overline{s_i}^n$, k and Reg, denoted by $\begin{array}{l} \Delta \succeq_{\overline{s_i}^n,k,Reg} \delta \text{ iff } \forall j \in \{0 \dots k\} : \sum_{Reg \ \rho = j} \ \Delta \ \rho \ \overline{s_i}^n \geq \delta \ j; \\ \bullet \ \mu \text{ is an upper bound for } m, \text{ denoted } \mu \succeq_{\overline{s_i}^n} m, \text{ iff } \mu \ \overline{s_i}^n \geq m; \text{ and} \end{array}$

• σ is an upper bound for s, denoted $\sigma \succeq_{\overline{s_i}^n} s$, iff $\sigma \overline{s_i}^n \ge s$.

Definition 5 (Correct signature). Let $(\Delta_g, \mu_g, \sigma_g)$ the signature of a function definition $g \ \overline{y_i}^l \ @ \ \overline{r'_j}^q = e_g$. This signature is said to be correct iff for all h, $h', k, \ \overline{v_i}^l, \ \overline{i_j}^q, v, \delta, m, s, \Gamma, t$ such that:

$$\begin{array}{ll} 1. & E_g = [\overline{y_i \mapsto v_i}^l, \overline{r'_j \mapsto i_j}^q, self \mapsto k+1] \vdash h, k+1, l+q, e_g \Downarrow h', k+1, v, (\delta, m, s). \\ 2. & \Gamma_g \vdash e_g : t \\ 3. & \forall i \in \{1 \dots l\} : s_i = size(h, v_i) \end{array}$$

then $\Delta_g \succeq_{\overline{s_i}^l,k,Reg} \delta|_k \land \mu_g \succeq_{\overline{s_i}^l} m \land \sigma_g \succeq_{\overline{s_i}^l} s$ for every region instantiation Reg consistent with h, E_g and Γ_g .

The following theorem establishes the correctness of the abstract interpretation for non-recursive functions.

Theorem 1. Let f a non-recursive context function. For each subexpression e of e_f and E, Σ , Γ , td, Δ , μ , σ , h, h', v, t, δ , m and s such that:

- 1. Every function call $g \ \overline{a_i}^l \ @ \ \overline{r'_j}^q$ in $e \ satisfies \ g \in dom \ \Sigma \ and \ \Sigma(g)$ is correct 2. $\llbracket e \rrbracket \ \Sigma \ \Gamma \ td = (\Delta, \mu, \sigma)$
- 3. $E \vdash h, k_0, td, e \Downarrow h', k_0, v, (\delta, m, s)$, belonging to (1)
- 4. $\Gamma \vdash e: t$

then $\Delta \succeq_{\overline{s_i}^n, k_0, Reg} \delta$, $\mu \succeq_{\overline{s_i}^n} m$ and $\sigma \succeq_{\overline{s_i}^n} s$, where $s_i = size(h, E_0 x_i)$ for each $i \in \{1 \dots n\}$, and each region instantiation Reg consistent with h, E and Γ such that dom $Reg = dom \Delta$.

Proof. By structural induction on e. The proof uses the fact that the size functions are monotonic, and relies on the correctness of the size analysis.

In order to prove the correctness of the algorithms shown in the following section for recursive functions we need the abstract interpretation to be monotonic with respect to function signatures.

Lemma 1. Let f be a context function. Given $\Sigma_1, \Sigma_2, \Gamma$, and td such that $\Sigma_1 \subseteq \Sigma_2$, then $[\![e]\!] \Sigma_1 \Gamma td \subseteq [\![e]\!] \Sigma_2 \Gamma td$.

Proof. By structural induction on e, because + and \sqcup are monotonic. \Box

6 Space Inference Algorithms

Given a recursive function f with n + m arguments, the algorithms for inferring Δ_f and σ_f do not depend on each other, while the algorithm for inferring μ_f needs a correct value for Δ_f . We will assume that μ_f , σ_f , and the cost functions in Δ_f , do only depend on arguments of f non-increasing in size. The consequence of this restriction is that the costs charged to regions, or to the stack, by the most external call to f are safe upper bounds to the costs charged by all the lower level internal calls. This restriction holds for the majority of programs occurring in the literature. Of course, it is always possible to design an example where the charges grow as we progress towards the leafs of the call-tree.

We assume that, for every recursive function f, there has been an analysis giving the following information as functions of the argument sizes $\overline{x_i}^n$:

$$\begin{split} splitExp_{f} & \left[e\right] = (e, \#) & \text{if } e = c, x, C \ \overline{a_{i}}^{n} \ @ r, \text{ or } g \ \overline{a_{i}}^{n} \ @ \ \overline{r_{j}}^{m} \text{ with } g \neq f \\ splitExp_{f} & \left[\left[f \ \overline{a_{i}}^{n} \ @ \ \overline{r_{j}}^{m}\right]\right] = (\#, f \ \overline{a_{i}}^{n} \ @ \ \overline{r_{j}}^{m}) \\ splitExp_{f} & \left[\left[\text{let } x_{1} = e_{1} \ \text{in } e_{2}\right]\right] = (e_{b}, e_{r}) \\ \text{where } (e_{1b}, e_{1r}) = splitExp_{f} & \left[e_{2}\right] \\ (e_{2b}, e_{2r}) = splitExp_{f} & \left[e_{2}\right] \\ e_{b} = \begin{cases} \# & \text{if } e_{1b} = \# \text{ or } e_{2b} = \# \\ \text{let } x_{1} = e_{1b} \ \text{in } e_{2b} \text{ otherwise} \end{cases} \\ & e_{r} = \begin{cases} \# & \text{if } e_{1r} = \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{if } e_{1r} = \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{if } e_{1r} \neq \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{if } e_{1r} \neq \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{if } e_{1r} \neq \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{if } e_{1r} \neq \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{if } e_{1r} \neq \# \text{ and } e_{2r} = \# \\ \text{let } x_{1} = e_{1r} \ \text{in } e_{2r} & \text{j } \text{otherwise} \end{cases} \\ splitExp_{f} \left[\left[\text{case}(!\right] x \text{ of } alt_{i}^{n}\right] = (e_{b}, e_{r}) \\ \text{where } \left(alt_{ib}^{n}, alt_{ir}^{n}\right) = unzip \left(map \ splitAlt_{f} \ \overline{alt_{i}}^{n}\right) \\ e_{b} = \begin{cases} \# & \text{if } alt_{ib} = \# \to \# \text{ for all } i \in \{1 \dots n\} \\ \text{case}(!) \ x \ \text{of } alt_{ib}^{n} \ \text{otherwise} \\ e_{r} = \begin{cases} \# & \text{if } alt_{ir}^{n} \ \text{otherwise} \\ e_{r} = \begin{cases} \# & \text{if } alt_{ir}^{n} \ \text{otherwise} \\ splitAlt_{f} \left[C \ \overline{x_{j}}^{n} \to e \right] = (alt_{b}, alt_{r}) \\ \text{where } (e_{b}, e_{r}) = splitExp_{f} e \\ alt_{b} = \begin{cases} \# \to \# & \text{if } e_{b} = \# \\ C \ \overline{x_{j}}^{n} \to e_{b} \ \text{otherwise} \\ alt_{r} = \begin{cases} \# \to \# & \text{if } e_{r} = \# \\ C \ \overline{x_{j}}^{n} \to e_{r} \ \text{otherwise} \\ alt_{r} = \begin{cases} \# \to \# & \text{if } e_{r} = \# \\ C \ \overline{x_{j}}^{n} \to e_{r} \ \text{otherwise} \end{cases} \end{cases} \end{cases}$$

Fig. 3. Function splitting a Core-Safe expression into its base and recursive cases

- 1. nc_f , an upper bound to the number of calls to f.
- 2. bf_f , the branching factor of f, i.e. maximum number of internal calls to f for every external call. If $bf_f = 1$ then f has linear recursion.
- 3. nr_f , an upper bound to the number of calls to f invoking f again. It corresponds to the internal nodes of f's call tree.
- 4. nb_f , an upper bound to the number of *basic* calls to f. It corresponds to the leaves of f's call tree.
- 5. len_f , an upper bound to the maximum length of f's call chains. It corresponds to the height of f's call tree.

In general, these functions are not independent of each other. For instance, if $bf_f = 1$ then $nr_f = nc_f - 1$, $nb_f = 1$, and $len_f = nc_f$. However, we will not assume a fixed relation between them. If this relation exists, it has been already used to compute them. We will only assume that each function is a correct upper bound to its corresponding runtime figure.

6.1 Splitting Core-Safe expressions

In order to do a more precise analysis, we separately analyse the base and the recursive cases of a *Core-Safe* function definition. Fig. 3 describes the functions *splitExp* and *splitAlt* which, given a *Safe* expression return the part of its body contributing to the base cases and the part contributing to the recursive cases. We introduce an empty expression # in order not to lose the structure of the original one when some parts are removed. These empty expressions charge null

$$\begin{split} splitBA_{f} \ \llbracket e \rrbracket = \llbracket \end{bmatrix} & \text{if } e = \#, c, x, C \ \overline{a_{i}}^{n} \ \textcircled{0} \ r, \text{ or } g \ \overline{a_{i}}^{n} \ \textcircled{0} \ \overline{r_{j}}^{m} \text{ with } g \neq f \\ splitBA_{f} \ \llbracket U_{i=1}^{n}e_{i} \rrbracket = concat \ [splitBA \ e_{i} \ | \ i \in \{1 \dots n\}] \\ splitBA_{f} \ \llbracket f \ \overline{a_{i}}^{n} \ \textcircled{0} \ \overline{r_{j}}^{m} \rrbracket = \llbracket (f \ \overline{a_{i}}^{n} \ \textcircled{0} \ \overline{r_{j}}^{m}, \#) \rrbracket \\ splitBA_{f} \ \llbracket t \ x_{1} = e_{1} \ \mathbf{in} \ e_{2} \rrbracket = A + H B \\ & \text{where} \ (e_{1b}, e_{1r}) = splitExp_{f} \ \llbracket e_{1} \rrbracket \\ (e_{2b}, e_{2r}) = splitExp_{f} \ \llbracket e_{2} \rrbracket \\ e_{1r,split} = splitBA \ \llbracket e_{1r} \rrbracket \\ e_{2r,split} = splitBA \ \llbracket e_{2r} \rrbracket \\ & A = \llbracket (\operatorname{let} \ x_{1} = e_{1} \ \operatorname{in} \ e_{2r,b}, \\ & \operatorname{let} \ x_{1} = \# \ \operatorname{in} \ e_{2r,a}) \ | \ (e_{2r,b}, e_{2r,a}) \in e_{2r,split} \rrbracket \\ & B = \begin{cases} \llbracket [\\ [(\operatorname{let} \ x_{1} = e_{1r,b} \ \operatorname{in} \ \#, \\ \\ \\ [(\operatorname{let} \ x_{1} = e_{1r,a} \ \operatorname{in} \ e_{2b}) \ | \ (e_{1r,b}, e_{1r,a}) \ \in \ e_{1r,split} \end{bmatrix} \\ otherwise \\ splitBA_{f} \ \llbracket \operatorname{case}(!) \ x \ \operatorname{of} \ \overline{C_{i} \ \overline{x_{ij}}^{n_{i}} \to e_{i}^{n}} \rrbracket = \\ \\ & \left[(\operatorname{case}(!) \ x \ \operatorname{of} \ \overline{C_{i} \ \overline{x_{ij}}^{n_{i}} \to e_{i,b}^{n}}, \operatorname{case}(!) \ x \ \operatorname{of} \ \overline{C_{i} \ \overline{x_{ij}}^{n_{i}} \to e_{i,a}^{n}} \right) \\ & \left[(e_{1,b}, e_{1,a}) \in splitBA_{f} \ \llbracket e_{1} \rrbracket], \dots, (e_{n,b}, e_{n,a}) \in splitBA_{f} \ \llbracket e_{n} \rrbracket \rrbracket \right] \end{cases} \end{split}$$

Fig. 4. Function splitting a Core-Safe expression into its parts executing before and after the last recursive call

costs to both the heap and the stack. Since it might be not possible to split a expression into a single pair with the base and recursive cases, we introduce expressions of the form $\sqcup e_i$, whose abstract interpretation is the upper bound to each single interpretation for e_i . It will also be useful to define another function which splits a Core-Safe expression into those parts that execute before and including the last recursive call, and those executed after the last recursive call, In Fig. 4 we define such function, called $splitBA_{f}$. In Fig. 5 we show a Full-Safe definition for a function split splitting a list, and the result of applying *splitExp* and *splitBA* to its Core-Safe version.

Algorithm for computing Δ_f 6.2

If e_f is f's body, let $(e_r, e_b) = splitExp_f \llbracket e_f \rrbracket$ and $(e_{bef}, e_{aft}) = (\bigsqcup_i e_{bef}^i, \bigsqcup_i e_{aft}^i),$ where $[\overline{(e_{bef}^i, e_{aft}^i)}^n] = splitBA_f[[e_r]]$. The idea here is to separately compute the charges to regions of the recursive and non-recursive parts of f's body, and then multiply these charges by respectively the number of internal and leaf nodes of f's call-tree.

- 1. Set $\Sigma f = ([]_f, 0, 0)$.

- 1. Set $\Delta f = ([1f, 0, 0)$. 2. Let $(\Delta_r, ..., ...) = \llbracket e_r \rrbracket \Sigma \Gamma (n+m)$ 3. Let $(\Delta_b, ..., ...) = \llbracket e_b \rrbracket \Sigma \Gamma (n+m)$ 4. Then, $\Delta_f \stackrel{\text{def}}{=} \Delta_r \mid_{\rho \neq \rho_{self}} \times nr_f + \Delta_b \mid_{\rho \neq \rho_{self}} \times nb_f$.

Lemma 2. If nr_f , nb_f , and all the size functions belong to \mathbb{F} , then all functions in Δ_f belong to \mathbb{F} .

Lemma 3. Δ_f is a correct abstract heap for f.

Proof. This is a consequence of nr_f , nb_f , and all the size functions being upper bounds of their respective runtime figures, and of Δ_r , Δ_b being upper bounds of respectively the f's call-tree internal and leaf nodes heap charges.

```

Fig. 5. Splitting a Core-Safe definition

Let us call $\mathbb{I}_{\Delta} : \mathbb{D} \to \mathbb{D}$ to an iteration of the interpretation function, i.e. $\mathbb{I}_{\Delta}(\Delta_1) = \Delta_2$, being Δ_2 the abstract heap obtained by initially setting $\Sigma f = (\Delta_1, 0, 0)$, then computing $(\Delta_{, -, -}) = \llbracket e_r \rrbracket \Sigma \Gamma (n+m)$, and then defining $\Delta_2 = \Delta \mid_{\rho \neq \rho_{self}}$.

Lemma 4. For all n, $\mathbb{I}^n_{\Delta}(\Delta_f)$ is a correct abstract heap for f.

Proof. This is a consequence of \mathbb{D} being a complete lattice, \mathbb{I}_{Δ} being monotonic in \mathbb{D} , and $\mathbb{I}_{\Delta}(\Delta_f) \sqsubseteq \Delta_f$. As \mathbb{I}_{Δ} is reductive at Δ_f then, by Tarski's fixpoint theorem, $\mathbb{I}_{\Delta}^n(\Delta_f)$ is above the least fixpoint of \mathbb{I}_{Δ} for all n. \Box

As the algorithm for μ_f critically depends on how good is the result for Δ_f , it is advisable to spend some time iterating the interpretation \mathbb{I}_{Δ} in order to get better results for μ_f .

6.3 Algorithm for computing μ_f

First, we infer the part of μ_f due to space charges to the *self* region of f. Let us call it μ_f^{self} . As the *self* regions for f are stacked, this part only depends on the longest f's call chain, i.e. on the height of the call-tree.

- 1. Set $\Sigma f = ([]_f, 0, 0)$.
- 2. Let $([\rho_{self} \mapsto \mu_{bef}], ..., ...) = [\![e_{bef}]\!] \Sigma \Gamma (n+m)$, i.e. the charges to ρ_{self} made by the part of f's body before (and including) the last recursive call.
- 3. Let $([\rho_{self} \mapsto \mu_{aft}], -, -) = [[e_{aft}]] \Sigma \Gamma (n+m)$, i.e. the charges to ρ_{self} made by the part of f's body after the last recursive call.
- 4. Let $([\rho_{self} \mapsto \mu_b], ..., ...) = [\![e_b]\!] \Sigma \Gamma (n+m)$, i.e. the charges to ρ_{self} made by the non-recursive part of f's body.

5. Then, $\mu_f^{self} \stackrel{\text{def}}{=} \mu_{bef} \times (len_f - 1) + \sqcup \{\mu_b, \mu_{aft}\}.$

Now, the inference of μ_f is done by provisionally assuming a signature for f in which f's heap needs are at least those due to charges to *self*, plus those due to charges to other regions. The latter are recorded in Δ_f .

- 1. Let $\mu_{prov} \stackrel{\text{def}}{=} |\Delta_f| + \mu_f^{self}$ 2. Set $\Sigma f = (\Delta_f, \mu_{prov}, 0)$. 3. Then, $(-, \mu_f, -) = \llbracket e_f \rrbracket \Sigma \Gamma (n+m)$.

Lemma 5. If the functions in Δ_f , len_f, and the size functions belong to \mathbb{F} , then μ_f belongs to \mathbb{F} .

Lemma 6. μ_f is a safe upper bound for f's heap needs.

Proof. This is a consequence of the correctness of the abstract interpretation rules, and of Δ_f , len_f , and the size functions being upper bounds of their respective runtime figures.

As in the case of Δ_f , we can define an interpretation \mathbb{I}_{μ} taking any upper bound μ_1 as input, and producing a better one $\mu_2 = \mathbb{I}_{\mu}(\mu_1)$ as output.

Lemma 7. For all n, $\mathbb{I}^n_{\mu}(\mu_f)$ is a safe upper bound for f's heap needs.

Proof. This is a consequence of $\mathbb F$ being a complete lattice, $\mathbb I_\mu$ being monotonic in \mathbb{F} , and \mathbb{I}_{μ} being reductive at μ_f .

Algorithm for computing σ_f 6.4

The algorithm for inferring μ_f traverses f's body from left to right because the abstract interpretation rules for μ need the charges to the previous heaps. For inferring σ_f we can do it better because its rules are symmetrical. The main idea is to count only once the stack needs due to calling to external functions.

- 1. Let $(-, -, \sigma_b) = [\![e_b]\!] \Sigma \Gamma (n+m)$.
- 2. Let $(-, -, \sigma_{bef}) = [e_{bef}] \Sigma[f \mapsto (-, -, \sigma_b)] \Gamma(n+m)$, i.e. the stack needs before the last recursive call, assuming as f's stack needs those of the base case. This amounts to accumulating the cost of a leaf to the cost of an internal node of f's call tree.
- 3. Let $(-, -, \sigma_{aft}) = [e_{aft}] \Sigma \Gamma (n+m)$.
- 4. We define the following function S returning a natural number. Intuitively it computes an upper bound to the difference in words between the initial stack in a call to f and the stack just before e_{bef} is about to jump to f again:

$$\begin{split} \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ \# \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{in} \ e_2 \rrbracket \ td \\ \mathcal{S} & \llbracket \mathbf{tt} \ x_1 = e_1 \ \mathbf{tt} \ \mathbf{tt} \ \mathbf{tt} \\ \mathcal{S} & \llbracket \mathbf{tt} \ \mathbf{tt} \ \mathbf{tt} \ \mathbf{tt} \ \mathbf{tt} \\ \mathcal{S} & \llbracket \mathbf{tt} \ \mathbf{tt} \\ \mathcal{S} & \llbracket \mathbf{tt} \ \mathbf{tt$$

Fig. 6. Full-Safe mergesort program

Function	Heap charges Δ	Heap needs μ	Stack needs σ
length(x)	[]	0	5x-4
	$\begin{bmatrix} \rho_1 \mapsto 1 \\ \rho_2 \mapsto \min(n, x - 1) + 1 \end{bmatrix}$		
split(n, x)		$2\min(n, x-1) + 3$	$9\min(n, x-1) + 4$
	$\left[\rho_3 \mapsto \min(n, x - 1) + 1 \right]$		
merge(x, y)	$\left[\rho_1 \mapsto \max(1, 2x + 2y - 5)\right]$	$\max(1, 2x + 2y - 5)$	11(x+y-4) + 20
$msort^1(x)$	$[\rho_2 \mapsto 2x^2 - 3x + 3]$	$\begin{array}{r} 0.31x^2 + 0.25x \log(x+1) + 14.3x \\ + 0.75 \log(x+1) + 10.3 \end{array}$	$\max(80, 13x - 10)$
$msort^2(x)$	$\left[\begin{array}{c} \rho_1 \mapsto \frac{x^2}{4} + x - \frac{1}{4} \\ \rho_2 \mapsto x^2 + x + 1 \end{array} \right]$	$0.31x^2 + 8.38x + 13.31$	$\max(80, 11x - 25)$
$msort^3(x)$	$\begin{bmatrix} \rho_1 \mapsto \frac{x^2}{8} + \frac{7x}{4} + \frac{9}{8} \\ \rho_2 \mapsto \frac{x^2}{2} + 4x + \frac{1}{2} \end{bmatrix}$	$0.31x^2 + 8.38x + 13.31$	$\max(80, 11x - 25)$

Fig. 7. Cost results for the mergesort program

5. Then, $\sigma_f = (\mathcal{S} \llbracket e_{bef} \rrbracket (n+m)) * \sqcup \{0, len_f - 2\} + \sqcup \{\sigma_{bef}, \sigma_{aft}, \sigma_b\}$

Lemma 8. If len_f , and all the size functions belong to \mathbb{F} , then σ_f belongs to \mathbb{F} .

Lemma 9. σ_f is a safe upper bound for f's stack needs.

Proof. This is a consequence of the correctness of the abstract interpretation rules, and of len_f being an upper bound to f's call-tree height. \Box

Also in this case, it makes sense iterating the interpretation as we did with Δ_f and μ_f , since it holds that $\mathbb{I}_{\sigma}(\sigma_f) \sqsubseteq \sigma_f$.

7 Case Studies

In Fig. 6 we show a *Full-Safe* version of the mergesort algorithm (the code for split was presented in Fig. 5) with the types inferred by the compiler. Region ρ_1 is used inside msort for the internal call split n' xs @ r1 r1 self, while region ρ_2 receives the charges made by merge. Notice that some charges to msort's *self* region are made by split. In Fig. 7 we show the results of our interpretation for this program as functions of the argument sizes. Remember that the size of a list (the number of its cells) is the list length plus one. The functions shown have been simplified with the help of a computer algebra tool. We show the fixpoints framed in grey. The upper bounds obtained for length, split, and merge are

Function	Heap needs μ	Stack needs σ
partition(p, x)	3x - 1	9x-5
append(x, y)	x - 1	$\max(8, 7x - 6)$
quicksort(x)	$3x^2 - 20x + 76$	$\max(40, 20x - 27)$
insertD(e, x)	1	9x - 1
insertTD(x,t)	2	$\frac{11}{2}t + \frac{7}{2}$
fib(n)	$2^n + 2^{n-3} + 2^{n-4} - 3$	$\max(10, 7n - 11)$
sum(n)	0	3n + 6
sumT(a, n)	0	5

Fig. 8. Cost results for miscellaneous Safe functions

sum 0 = 0	<pre>insertTD x Empty! = Node (Empty) x (Empty)</pre>
sum n = n + sum (n - 1)	insertTD x (Node lt y rt)!
	x == y = Node lt! y rt!
<pre>sumT acc 0 = acc</pre>	x > y = Node lt! y (insertTD x rt)
sumT acc n = sumT (acc + n) (n - 1)	x < y = Node (insertTD x lt) y rt!

Fig. 9. Two summation functions and a destructive tree insertion function

exact and they are, as expected, fixpoints of the inference algorithm. For msort we show three iterations for Δ and σ , and another three for μ by using the last Δ . The upper bounds for Δ and μ are clearly over-approximated, since a term in x^2 arises which is beyond the actual space complexity class $O(x \log x)$ of this function. Let us note that the quadratic term's coefficient quickly decreases at each iteration in the inference of Δ . Also, μ and σ decrease in the second iteration but not in the third. This confirms the predictions of lemmas 4 and 7.

We have tried some more examples and the results inferred for μ and σ after a maximum of three iterations are shown in Fig. 8, where the fixpoints are also framed in grey. There is a quicksort function using two auxiliary functions partition and append respectively classifying the list elements into those lower (or equal) and greater than the pivot, and appending two lists. We also show the destructive insertD function of Sec. 2, and a destructive version of the insertion in a search tree (its code is shown in Fig. 9). Both consume constant heap space. The next one shown is the usual Fibonacci function with exponential time cost, and using a constructed integer in order to show that an exponential heap space is inferred. Finally, we show two simple summation functions (its code also appears in Fig. 9), the first one being non-tail recursive, and the second being tail-recursive. Our abstract machine consumes constant stack space in the second case (see [11]). It can be seen that our stack inference algorithm is able to detect this fact.

8 Related and Future Work

Hughes and Pareto developed in [7] a type system and a type-checking algorithm which guarantees safe memory upper bounds in a region-based first-order functional language. Unfortunately, the approach requires the programmer to provide detailed consumption annotations, and it is limited to linear bounds. Hofmann and Jost's work [6] presents a type system and a type inference algorithm which, in case of success, guarantees linear heap upper bounds for a first-order functional language, and it does not require programmer annotations.

The national project AHA [15] aims at inferring amortised costs for heap space by using a variant of sized-types [8] in which the annotations are polynomials of any degree. They address two novel problems: polynomials are not necessarily monotonic and they are *exact* bounds, as opposed to approximate upper bounds. Type-checking is undecidable in this system and in [16, 14] they propose an inference algorithm for a list-based functional language with severe restrictions in which a combination of testing and type-checking is done. The algorithm does not terminate if the input-output size relation is not polynomial.

In [2], the authors directly analyse Java bytecode and compute safe upper bounds for the heap allocation made by a program. The approach uses the results of [1], and consists of combining a code transformation to an intermediate representation, a cost relations inference step, and a cost relations solving step. The second one combines ranking functions inference and partial evaluation. The results are impressive and go far beyond linear bounds. The authors claim to deal with data structures such as lists and trees, as well as arrays. Two drawbacks compared to our results are that the second step performs a global program analysis (so, it lacks modularity), and that only the allocated memory (as opposed to the live memory) is analysed. Very recently [3] they have added an escape analysis to each method in order to infer live memory upper bounds. The new results are very promising.

The strengths of our approach can be summarised as follows: (a) It scales well to large programs as each *Safe* function is separately inferred. The relevant information about the called functions is recorded in the signature environment; (b) We can deal with any user-defined algebraic datatype. Most of other approaches are limited to lists; (c) We get upper bounds for the *live* memory, as the inference algorithms take into account the deallocation of dead regions made at function termination; (d) We can get bounds of virtually any complexity class; and (e) It is to our knowledge the only approach in which the upper bounds can be easily improved just by iterating the inference algorithm.

The weak points that still require more work are the restrictions we have imposed to our functions: they must be non-negative and monotonic. This exclude some interesting functions such as those that destroy more memory than they consume, or those whose output size decreases as the input size increases. Another limitation is that the arguments of recursive *Safe* functions related to heap or stack consumption must be non-increasing. This limitation could be removed in the future by an analysis similar to that done in [1] in which they maximise the argument sizes across a call-tree by using linear programming tools. Of course, this could only be done if the size relations are linear.

Another open problem is inferring *Safe* functions with region-polymorphic recursion. Our region inference algorithm [13] frequently infers such functions, where the regions used in an internal call may differ from those used in the external one. This feature is very convenient for maximising garbage (i.e. allocations to the *self* region) but it makes more difficult the attribution of costs to regions.
